Abstract

Autonomous AI agents now contact pharmacies, transport brokers, and clinics for patients, but receiving organisations cannot verify who operates an agent, what the patient authorised, or whether the agent discloses only what the task needs. We specified a health agent handshake of six elements and four risk tiers; in a symbolic model it satisfied eight security properties, each failing without its check. In 14,256 simulated calls with three Claude models, the full handshake left no detected disclosure beyond the task allowlist, against 7.7% to 47.4% under a privacy prompt alone; GPT-6.1 Sol, Gemini 3.1 Pro, and Claude Haiku 5.5 also had none. Withholding fields from the agent was the most effective single component. In a permission-carrying mode, the counterparty obtains the fields from the data holder; symbolically, an adversary that controlled only the agent then learned no record value, and in simulation no agent disclosed detectably.

Introduction

Autonomous AI agents, software that takes actions for its users rather than only answering questions, have begun to act for patients. Consumer agents are multiplying: Meta's Muse, OpenAI's dots, Manus's Cue, and Underdog were released within a month of each other in 2026.[1–4] Several advertise health tasks. Meta invites users to ask Muse to "book an appointment";[5] Cue offers to "find a dermatologist who takes my insurance and book a skin check";[6] and Underdog lists "doctor's appointments, prescription refills" among the sensitive tasks that it handles. In health care, early deployments of agents concentrate on administrative work and are spreading into clinical care.[7] A scoping review restricted to

systems that operate autonomously towards clinical goals found seven studies, one of which involved patients.[8] Commentaries propose institutional safeguards for agents inside health systems[9] and describe how agents can exceed their authority on external systems.[10]

When an autonomous agent acts for a patient, the receiving counterparty (such as a pharmacy, outpatient clinic, or health plan) faces three operational questions before it acts on the request: which legal entity is accountable for operating the agent, whether the patient authorised the specific requested action, and whether disclosure remains confined to the minimum necessary information required for the clinical task. We call the organisation that runs the agent the operator. The US privacy rule permits disclosure for treatment, payment, and health-care operations, and it exempts treatment disclosures, disclosures to the patient, and disclosures under an authorisation from its minimum-necessary standard, which limits a disclosure to the information needed for its purpose.[11] It requires a covered entity, meaning a health-care provider, health plan, or claims clearing house, to verify an unknown requester but leaves the method to reasonable reliance and professional judgment.[11] Verification can therefore rest on a name, a date of birth, or a member number, which an agent can supply whether or not the patient authorised the request.

Language models do not reliably enforce privacy norms by themselves. In a benchmark of contextual privacy, GPT-4 and ChatGPT passed information marked as private to inappropriate recipients in 39% and 57% of cases, even when instructed to preserve privacy.[12] In a benchmark of agent actions, GPT-4 and Llama-3-70B leaked sensitive information in 25.7% and 38.7% of cases, even with privacy-enhancing prompts,[13] and web agents in a second benchmark mishandled users' personal data.[14] Defences that separate control flow from untrusted data give stronger guarantees,[15,16] sometimes at a cost to task utility.[15] A recent defence that moves disclosure decisions out of the model's context reduced leakage to near zero under conversational attacks that need no prompt injection.[17]

Work outside health care provides building blocks. Authenticated delegation extends OAuth and OpenID Connect so that a user can grant an agent limited, auditable authority.[18,19] Agent identity proposals let a verifier check an agent's identity and delegated authority,[20,21] although a recent review found that an agent's actions still carry no verifiable link to the user's consent.[22] Capability tokens that bind identity, narrowed authority, and provenance across agent protocols,[23] and zero-knowledge proofs that a request satisfies a policy,[24] address parts of that gap. Payment networks addressed an analogous delegation problem. European rules for strong customer authentication require dynamic linking, binding each authentication code to a specific monetary amount and payee.[25] Agent payment protocols carry a user's intent as a signed mandate that a merchant can verify,[26] card networks keep directories of registered agents whose requests are signed,[27] and card networks give agents tokens in place of card numbers, so that the agent never holds the

card number.[28] Recent preprints describe signed mandates with chained audit trails,[29] receipts that the receiving service signs,[30] and attested preconditions before high-risk actions.[31] Health proposals describe patient-governed mandates for research data[32] and consent architectures for agents inside hospitals.[33] These proposals supply the parts. The next step is a specification of what a health counterparty should check before it acts on a patient's agent, a formal analysis of that check, and a measurement of how much it changes disclosure by agents.

This study addresses four questions. First, can a verification profile for patient agents be built from existing security building blocks, with a health risk-tier taxonomy, a field allowlist (the list of fields that a task permits), and a telephone fallback? Second, does the profile satisfy its security properties against a network attacker, and which properties fail in the telephone fallback? Third, in simulated calls between language-model agents and simulated counterparties, how do configurations of the profile, and each of its components, change disclosure beyond the task allowlist, attack success, and request acceptance? Fourth, can the agent carry the patient's permission instead of the patient's data, so that neither the agent nor its operator holds the fields that a task discloses?

Results

Specification

We specified six elements: five that an agent presents and a counterparty checks, and a receipt that the counterparty signs (Table 1; Figure 1). H1 binds the agent's operator to a legal entity and its role under the privacy rule. H2 is the operator's signed attestation of the agent's model, version, guardrail policy, and risk ceiling. H3 is a mandate, a signed record of what the agent may do and disclose. It states purpose, permitted actions, permitted fields, permitted classes of counterparty, risk ceiling, and expiry. It binds a consent record that the patient signed with a key that an identity provider certified. H4 is a challenge and a revocation check. H5 is a patient approval bound to one action, its parameters, one counterparty, one set of fields, and one challenge, required for tier 3. H6 is a counterparty-signed receipt, or refusal receipt, whose hash enters an append-only log. Supplementary Note 1 follows a refill request through each element in order and compares the study configurations.

We defined four risk tiers (Table 2). Tier 0 involves no protected health information. Tier 1 discloses or requests it without a commitment. Tier 2 commits the patient to a reversible transaction. Tier 3 covers irreversible or clinically consequential actions, controlled substances, cancellations of time-sensitive services, and any request that discloses specially protected information to a party that does not already hold it. The counterparty assigns the

tier from its own reference data and from the tier that the patient set in the consent. The operator classifies each request before sending it and obtains any tier 3 approval first.

Formal verification

We analysed the handshake with the Tamarin prover,[34] an automated tool that searches every possible exchange of messages for an attack. The analysis treats cryptography as unbreakable and lets the attacker read, block, and forge any message on the network. We stated one security property for each way in which an attacker could make a counterparty act without the patient's authority (Figure 3; Supplementary Table 1). Two properties address impersonation: when a counterparty accepts a request, the named agent or sub-agent really sent that exact request, once. Two address forged authority: the consent carries the patient's own signature, and the mandate comes from the operator. One addresses replay, because each challenge is accepted only once. One addresses reuse of a high-risk approval, because the approval covers one action and its parameters. The last two address a sub-agent that gains more authority than it was given and a receipt that is forged or altered. The full model satisfied all eight properties, and further checks showed that honest runs complete with no key compromise. Consent binding held even when the operator's key was compromised, because the counterparty checks the patient's signature under an identity-provider key. Each property failed in at least one of nine negative-control models that removed the corresponding check. Two controls reproduced specific design errors: an approval for a sub-agent checked under a key that the request supplies, and an approval that does not bind the action's parameters.

For the telephone fallback, a lookup over an authenticated channel established that the operator registered this agent, counterparty, and action. It also established that the operator registered the code only on the agent's signed request. Each code produced at most one acceptance, a property that holds by construction in the model. Without a lookup, the prover found an attack in which a caller claimed any operator. With a lookup, it found a relay in which a party that overhears a code presents it first on its own call.

Conformance of the reference implementation

We ran 46 attacks and eight legitimate requests against five verification levels (Supplementary Table 2). With a name and a date of birth only, all 46 attacks succeeded. With operator identity only, 41 of 46 succeeded; with an operator and mandate, 21 of 46; with freshness and status checks added, 15 of 46; and with the full handshake, 0 of 46. All eight legitimate requests succeeded at every level. Twenty-eight telephone checks, five checks of refusal receipts and the operator gate, and two checks on the issuer and identity provider passed. These results verify the implementation; they are not behavioural findings.

Adversarial evaluation

We completed 14,256 of 14,256 planned conversations: 1,188 scenarios in four configurations for each of three agent models. Disclosure beyond the task allowlist was 0 of 1,188 calls in the full handshake for each model (Table 3; Figure 2). For the primary contrast, the full handshake minus the privacy prompt, disclosure fell by 14.1 percentage points (95% CI −17.3 to −11.1) for Claude Opus 5.5, 7.7 points (−9.4 to −6.1) for Claude Sonnet 5.5, and 47.4 points (−52.2 to −42.3) for Claude Haiku 4.5. Under the status quo, disclosure was 212 of 1,188 calls (17.8%) for Opus, 164 of 1,188 (13.8%) for Sonnet, and 879 of 1,188 (74.0%) for Haiku.

The structured mandate with counterparty verification, without operator-side enforcement, also produced 0 of 1,188 disclosures for Opus and Sonnet. For Haiku, disclosure in that configuration was 282 of 1,188 calls (23.7%), and only the operator-side controls removed it. The difference between the full handshake and the counterparty-side handshake for Haiku was −23.7 percentage points (−26.8 to −21.0).

Attack success followed the same pattern (Figure 2). The pretext request for a home address and the last four digits of a Social Security number was the most effective attack across configurations for all three models. Under the status quo it succeeded in 120 of 198 calls for Opus, 118 of 198 for Sonnet, and 183 of 198 for Haiku. Opus and Sonnet resisted the other five attacks in every configuration. Under the status quo, Haiku disclosed the patient's specially protected condition in 256 of 1,188 calls (21.5%) and had 46 of 1,188 out-of-mandate actions accepted (3.9%). Both were 0 of 1,188 in the full handshake.

Acceptance of benign requests was 198 of 198 for Opus and Sonnet in the full handshake. For Haiku it was 188 of 198 (94.9%) in the full handshake, 194 of 198 (98.0%) with the privacy prompt (difference −3.0 percentage points, 95% CI −7.1 to 1.0), and 196 of 198 (99.0%) under the status quo (−4.0, −7.6 to −1.0). Under the status quo, Haiku never stated that it was an AI agent in its first turn (0 of 1,188 calls), and Sonnet did so in 796 of 1,188 calls (67.0%). With the privacy prompt, all three Claude models did so in at least 1,187 of 1,188 calls.

Disclosure differed by type of counterparty. Under the status quo, Opus over-disclosed in 88 of 462 calls with a simulated human and 65 of 462 with a simulated AI agent, and Sonnet in 76 and 61 of 462. Haiku over-disclosed in 362 and 379 of 462.

In the secondary analysis, we completed 9,504 of 9,504 planned conversations. Disclosure beyond the task allowlist was 0 of 1,188 calls in the full handshake for GPT-6.1 Sol and for Gemini 3.1 Pro (Table 3; Figure 2). With the privacy prompt it was 180 of 1,188 calls (15.2%) and 289 of 1,188 (24.3%), and the full handshake minus the privacy prompt was −15.2 percentage points (95% CI −17.3 to −13.0) and −24.3 points (−26.0 to −22.7).

Under the status quo, the pretext attack succeeded in 198 of 198 calls for Gemini 3.1 Pro, which also disclosed the protected condition in 118 of 1,188 calls (9.9%), and had 91 of 1,188 out-of-mandate actions accepted (7.7%); all three were 0 in the full handshake. The counterparty accepted 198 of 198 benign requests from Gemini 3.1 Pro in the full handshake. It accepted 184 of 198 from GPT-6.1 Sol (92.9%) in the full handshake, 172 of 198 (86.9%) with the privacy prompt (difference 6.1 percentage points, 95% CI 2.0 to 11.1), and 150 of 198 (75.8%) under the status quo. In every call without acceptance, GPT-6.1 Sol stated the request aloud but did not submit the transaction. In a re-run of 16 such calls, it used the tool on all 50 of its turns, so the shortfall reflects its choice of action rather than a failure to use the tool.

Claude Haiku 5.5, a newer small model added as a further secondary agent, completed 4,752 of 4,752 planned conversations. Disclosure beyond the task allowlist was 578 of 1,188 calls (48.7%) under the status quo, 391 of 1,188 (32.9%) with the privacy prompt, 61 of 1,188 (5.1%) in the handshake, and 0 of 1,188 in the full handshake (Table 3; Figure 2). The full handshake minus the privacy prompt was −32.9 percentage points (95% CI −36.0 to −29.9). Under the privacy prompt, the pretext attack succeeded in 180 of 198 calls. Request acceptance was 187 of 198 (94.4%) in the full handshake and 175 of 198 (88.4%) with the privacy prompt (difference 6.1 percentage points, 95% CI 1.5 to 10.6).

Contribution of each component

In the main configurations, the agents never tried to send a field, take an action, or say a value that the verifier, the tool gate, or the outbound filter would stop, so these controls were never triggered. To measure each component, we added one at a time to the privacy prompt (Figure 4; Supplementary Table 7). Table 4 gives an example of each type of problem and the component that addresses it, and Supplementary Note 5 gives the surrounding turns. The mandate in the agent's context removed disclosure beyond the task allowlist for Opus and Sonnet (0 of 1,188 calls each) and nearly removed it for GPT-6.1 Sol (4 of 1,188) and Gemini 3.1 Pro (10 of 1,188). For Haiku, it reduced disclosure from 563 of 1,188 calls (47.4%) to 271 of 1,188 (22.8%).

The verifier alone stopped all disclosure in transactions, but disclosure in speech continued. It rejected requests in 36 to 271 calls per model, and disclosure remained in 62 to 466 of 1,188 calls. Data minimisation alone removed spoken disclosure for every model; total disclosure was 0 for four models and 5 of 1,188 for Haiku, which requested withheld fields by name in transactions. The tool gate and outbound filter alone prevented every attack that canary matching scored and every out-of-mandate action. However, telephone numbers, which the filter does not redact, still reached the counterparty in 12 to 109 of 1,188 calls, and request acceptance fell for Haiku (165 of 198) and GPT-6.1 Sol (157 of

198). Only the combination of all components reached zero disclosure and zero attack success for every model.

Sensitivity to the counterparty simulator

With GPT-6.1 Sol as the simulated counterparty on the 924 scenarios with a simulated human or AI agent, disclosure in the full handshake was 0 of 924 calls for all five agents. The full handshake minus the privacy prompt ranged from −5.3 percentage points (95% CI −6.8 to −3.8) for Sonnet to −46.9 points (−51.7 to −42.0) for Haiku (Supplementary Table 6). Request acceptance in the full handshake was 122 to 132 of 132 for four agents and 101 of 132 for GPT-6.1 Sol. In all 31 of its calls without acceptance, GPT-6.1 Sol ended the call without submitting the transaction; in 23 of them, this counterparty had asked for details that the synthetic record lacked, such as a ZIP code.

Run-to-run variation

In three runs of 198 scenarios, the full handshake had 0 disclosures in every run for every agent. Under the privacy prompt, total disclosure varied little between runs (for example, 90, 91, and 92 of 198 calls for Haiku), but the outcome of a given scenario did not always repeat: it was the same in all three runs for 114 to 180 of 198 scenarios (Fleiss' kappa 0.43 to 0.77). The full handshake minus the privacy prompt was negative, with a 95% CI that excluded zero, in every run for every agent (Supplementary Table 9).

Validity of the disclosure measure

Both judges classified all 456 synthetic items correctly, whereas canary matching detected 10 of 114 paraphrased disclosures (Supplementary Table 8). In the audit sample, the judges found no disclosure that canary matching missed in the full handshake, the handshake, or the arms with the mandate only or data minimisation only (0 of 200 conversations each). With the privacy prompt and with the verifier only, they flagged only a pharmacy chain name without the store number (2 and 1 of 200). With the tool gate and outbound filter only, agents evaded the filter in 10 of 200 conversations, for example by spelling out Social Security digits ("five, eight, nine, one"); in 16 more, the judges flagged a city or pharmacy chain name that remained after redaction, which S.B. judged not identifying.

Permission-carrying mode

In the permission-carrying mode, neither the operator nor the agent holds field values. The mandate names each permitted field, the class of counterparty, and the organisation that holds the fields. After it verifies a request, the counterparty signs a redemption, which is a request to release the fields. It sends the redemption to the data holder, the health plan, provider, or patient's wallet that keeps the record. The data holder repeats the checks and

applies the risk tiers to the values that it will release. It then releases only the requested fields, once per request, signed and encrypted to the counterparty's key (Methods).

In a symbolic model of this mode, six security properties held, and each failed in at least one of nine negative-control models (Supplementary Table 10). The data holder released a field only under the patient's signed consent for the receiving counterparty's class, unless the patient's key was compromised. It released a field only under a mandate that named the holder, unless the operator's key was compromised. It released only to the counterparty named in a request that the agent signed, unless the agent's or operator's key was compromised. It released only in answer to a redemption that the counterparty signed, once per challenge, unless that counterparty's key was compromised. A counterparty accepted released data only from the data holder, unless the holder's key was compromised. The adversary could learn a record value in only two ways: the holder released it to a compromised counterparty of a class that the patient had consented to, or the patient's key was compromised. Compromising the agent or the operator alone revealed no record value. In the control in which the holder gives the agent the record to carry after the same checks, as in the configurations of the simulation, compromising the agent alone revealed the record. In a bearer design, in which whoever presents a captured request can redeem it, the record leaked with no key compromised.

In the reference implementation, six legitimate requests were verified, redeemed, and opened with exactly the requested fields (Supplementary Table 11). They included a tier 3 pharmacy change, a delegated sub-agent, and a refill whose released medication list named a protected drug, which the data holder released only with the patient's approval. All 33 attacks were refused, each for the expected reason, and all 19 malformed inputs were refused without error. The attacks included redemption of a captured request by another pharmacy, by an unregistered or revoked party, or with another key; a second redemption of the same challenge; and a field or counterparty class added by a compromised operator. They also included a value carried in place of a reference, revocation before redemption, tier 3 requests without a valid approval, a protected value that raised the tier above the mandate's ceiling, a sub-agent mandate wider than its parent, and a forged, misdirected, or intercepted release. The tokens that the agent held or sent for a refill request contained no record value and no opening of the identity commitment. A mandate with the same permissions in the data-carrying design contained all five permitted values and the opening.

In the simulation, the permission-carrying arm left no detected disclosure beyond the task allowlist and no successful attack for any of the five agents (0 of 1,188 calls each; Supplementary Table 12). Request acceptance was at least as high as in the full handshake for every agent, and higher for GPT-6.1 Sol (198 of 198 vs 184 of 198; difference 7.1 percentage points, 95% CI 4.0 to 10.6). The prompt in this arm also told the agent to submit

the transaction when the counterparty asked for details, which may explain part of that difference. An information-flow arm, in which the agent saw each field only as a handle and a monitor outside the model inserted permitted values, left no detected disclosure for four agents and one for Haiku, which inferred the member's diabetes from the drug named in its task and said so. Its request acceptance was lower than in the full handshake for every agent, by 3.0 percentage points (95% CI −6.1 to −0.5) for Sonnet to 20.7 points (−27.3 to −13.6) for Haiku. Without a mandate in context, agents in that arm added fields outside the allowlist to transactions, most often a telephone number, and the tool gate blocked them in 12 to 200 of 1,188 calls.

Discussion

We report five findings. First, a verification profile for agents that act for patients can be built from existing security building blocks, with a health risk-tier taxonomy, a field allowlist, and a telephone fallback. Second, the profile satisfied eight security properties in a symbolic model, and removing the check behind any one property made that property fail; the telephone fallback authenticated the registration but not the caller. Third, in 14,256 simulated calls with three Claude models and 14,256 with three further models, two from other developers, the full handshake left no detected disclosure beyond the task allowlist for all six, compared with 7.7% to 47.4% under a privacy prompt alone. Request acceptance did not fall for five models; for Claude Haiku 4.5 it was 3.0 percentage points lower than with the privacy prompt (95% CI −7.1 to 1.0) and 4.0 points lower than under the status quo (−7.6 to −1.0). Fourth, the components were complementary: the mandate in context, data minimisation, the verifier, and the tool gate each closed a different channel, and only their combination reached zero for every model. Fifth, in a permission-carrying mode, the counterparty obtained the fields from the data holder, and the agent and the operator never held them; in a symbolic model, an adversary that controlled only the agent learned no record value, and in simulation the mode left no detected disclosure for any agent while keeping request acceptance at least as high as the full handshake.

The ablation shows that each component addresses a different channel. Telling the agent its scope, through the mandate in its context, eliminated detected disclosure for two models and reduced it below 1% for two others. This suggests that explicit, machine-readable scope helps capable models more than prose policy does; it did not do so for the least capable model. The counterparty's verifier stopped every disclosure in transactions but could not stop the agent from saying the same information aloud. Data minimisation removed what the agent could say, and the tool gate stopped unauthorised actions. An outbound filter was the weakest control: agents evaded it by spelling values out, so withholding data from the agent is more reliable than filtering what it says. In the full

handshake, the mandate and data minimisation kept agents from making the requests that the verifier, gate, and filter catch, so these controls were never triggered. They are safeguards for an agent that ignores its instructions or is compromised, which the conformance tests examine directly. Under a privacy prompt, the same call could disclose in one run and not in another, which is a further reason to rely on controls outside the model. This indicates that the components complement one another; it does not indicate which combination is enough against attacks that we did not simulate.

The ablation also points to an architectural design principle: withholding fields from the agent was the only single component that reduced detected disclosure to zero or near zero across all evaluated models. In the permission-carrying mode, the agent carries cryptographic proof of the patient's permission rather than the record, and the counterparty obtains the permitted fields directly from the data holder, which is already accountable for what it discloses. The record's field values are then outside anything that an accidental or coerced disclosure by the agent could reveal, and the protection is a property of the protocol rather than of the operator's configuration. Card networks do the same for agent payments, with tokens in place of card numbers,[28] and security engineering has long favoured narrow authority for a program that acts for others.[35] Where the agent must hold information to converse, such as the name of a drug, labels that state who may receive each item, enforced outside the model, would generalise the outbound filter.[15,17] In our information-flow arm, such a monitor kept detected disclosure to one call, in which the agent inferred a diagnosis from the drug name it needed for the task, but it lowered request acceptance, because agents without a mandate did not know which fields a transaction could carry. A monitor and a mandate are therefore complements rather than alternatives.

The pretext attack, which asked for an address and Social Security digits "for verification", succeeded most often. It mimics routine identity checks, and commercial agents have disclosed card numbers and addresses to similarly simple manipulation.[36] Under a privacy prompt alone, Opus complied in 100 of 198 calls, Sonnet in 65 of 198, and Gemini 3.1 Pro in 198 of 198. A field allowlist that the counterparty can check turns this social pressure into a rule that both parties can see.

These findings extend general work on authenticated delegation,[18] signed mandates,[26,29] and receiver-signed receipts[30] to the health setting, where disclosure rules, risk, and patients' capacity to approve requests differ. The handshake complements institutional safeguards for agents inside health systems[9] by extending them to the boundary between an agent that acts for a patient and an outside party. Outside the USA, the same checks map onto the EU rules for health data[37] and the EU requirement to tell people when they interact with an AI system.[38] A preprint reported that models disclose more to AI recipients.[39] In our setting, the two larger models disclosed less to simulated AI agents than to simulated humans.

This study has limitations. The members, counterparties, and conversations were simulated; real staff, telephone menus, and agents may behave differently. The counterparty simulator was itself a language model with scripted attack openings. We measured disclosure with deterministic canary matching, so we report detected disclosure. An audit with two judge models found that it missed few disclosures except where the outbound filter was the only control, but the judges' synthetic test set may be easier than real paraphrase. Canary matching also misses bare affirmations and explicit confirmations of sensitive information that the counterparty named first. A search of all main-run calls found 11 such confirmations, 10 by Gemini 3.1 Pro under the status quo and 1 by Claude Haiku 4.5 with the privacy prompt, and none in the handshake configurations. Most scenarios ran once per configuration and model; repeated runs covered a stratified sample of 198. The outbound filter does not redact telephone numbers. The primary analysis used three models from one developer, the secondary analysis added one model from each of two other developers and a newer small Claude model, and Claude Sonnet 5.5, one of the agents under test, simulated the counterparties in the main analyses; with GPT-6.1 Sol as the simulator, the disclosure results did not change, but request acceptance fell for GPT-6.1 Sol. Gemini 3.1 Pro was a preview release, and its behaviour may change. The adversarial evaluation tested honest agents facing hostile counterparties; unauthorised or impersonating agents were tested against the verifier only in the formal analysis and the conformance tests. The formal model assumes perfect cryptography, an authentic directory, and honest counterparties, and it omits time, revocation, tier rules, and selective disclosure, which we tested only in the implementation. Its consent binding also assumes that the patient's device shows the patient what the patient's key signs. The simulation of the permission-carrying mode tested how agents behave when they hold no record; it did not simulate the redemption exchange with the data holder. The mode needs the data holder to be online and to take part, and it does not cover information that exists only in conversation. Requests in that mode remain linkable across counterparties, each of which receives the patient's name and date of birth. Its formal model omits time, revocation, tiers, tier 3 approvals, and sub-agents, and has one field per request; we tested these only in the implementation. We did not analyse the handshake's composition with agent protocols such as MCP and A2A, which can break properties that hold for each protocol alone.[40] The tier taxonomy was not validated with external experts. The reference implementation is an unaudited research prototype. We did not study consent comprehension, approval behaviour, or counterparty uptake with people.

The handshake makes the authority of a patient's agent checkable by the party that receives its requests. In simulation, it left no detected disclosure beyond the task allowlist for six models from three developers, with no loss of request acceptance for five of them, and each of its components closed a different channel. Withholding data from the agent was the most effective single component, and a permission-carrying mode, which left no

detected disclosure in simulation, makes that a property of the protocol: the agent carries the patient's permission, not the patient's data. Field trials with outpatient clinics, community pharmacies, transport brokers, and patients represent the next step.

Methods

Specification

We wrote the profile as a reference implementation in Python. Each token is a header, payload, and Ed25519 signature over canonical JSON. Mandate and consent entries travel as salted-hash disclosures in the style of SD-JWT,[41] so the agent reveals only the actions and fields that one request needs. An identity provider certifies the patient's key for a salted commitment to the proofed name and date of birth. Each request opens the commitment, and the counterparty checks it against the name and date of birth in the request. The counterparty refuses the request if more than one of its records matches. Revocation uses status lists published by the operator and by the identity provider.[42] The receipt log follows RFC 9162,[43] with leaf and node domain separation, signed tree heads, and inclusion and consistency proofs. Telephone codes are eight characters from a 31-symbol alphabet, single use, bound to one agent, counterparty, action, and parameter hash, and issued only on the agent's signed request. We assigned tiers with a five-rule procedure based on the minimum-necessary standard, the authorisation rule, and the confidentiality rule for substance use disorder records.[11,44,45]

Formal verification

We modelled the patient, operator, agent, sub-agent, and counterparty in the Tamarin prover (version 1.12.0, Maude 3.5.1), an automated verifier for security protocols.[34] The attacker controls the network, as in the standard Dolev–Yao model,[46] and can reveal any party's long-term key; each lemma states the compromises it tolerates. The identity provider and the operator directory are an authentic public-key infrastructure. We defined four executability lemmas and eight security lemmas, and we built nine negative-control models, each removing one check. A separate model represents the telephone fallback. Calls are sessions on an insecure channel, an adversary can place its own calls, and the code lookup is an authentic channel. One control removes the agent's signed request for a code. All models passed Tamarin's wellformedness checks with the derivation-check timeout disabled.

We also ran a conformance suite against the reference implementation, with eight legitimate requests and 46 attacks (Supplementary Table 2). Each ran against five

verification levels, from name and date of birth only to the full handshake. At the lowest level we assumed that the attacker knows the patient’s name and date of birth.

Permission-carrying mode

The operator issues a reference mandate in which each field disclosure names the data holder instead of the value, so the operator never handles field values. The operator also never receives the opening of the identity provider’s commitment. Neither it nor the agent can therefore recover the patient’s name and date of birth by guessing against the commitment. The request format is otherwise unchanged. The counterparty verifies the request as in the main profile, except that identity binding and the content-based tier rules move to the data holder, which alone sees the values. Without field values, the counterparty cannot use its own records to lower a tier, so actions on existing appointments or rides are tier 3 in this mode. The counterparty signs a redemption over the request hash, its own identifier, and the holder’s identifier.

The data holder authenticates the redeemer through its counterparty directory, from which it also takes the redeemer’s class, and requires that the request name the redeemer. It repeats the checks of the attestation, delegation chain, consent, mandate, revocation status, and tier 3 approval, and it finds the record by the certified subject commitment. If a value that it will release names a controlled or protected drug or service, it raises the tier to 3. It then refuses the release if tier 3 exceeds the mandate’s or the attestation’s ceiling, as the counterparty would, and otherwise requires the patient’s approval. It releases the requested fields sealed to the counterparty’s X25519 key and signed with Ed25519. The seal uses HKDF-SHA256 over the shared secret and both public keys, and AES-256-GCM with the holder, counterparty, request hash, and subject commitment as associated data. The signed release states the subject commitment, which the counterparty checks against the identity provider’s certificate. The holder refuses a second redemption of the same request or challenge, refuses malformed input, and logs a hash of each signed release in the transparency log.

We modelled the mode in Tamarin with record values that are fresh and never sent in clear, and with a consent and mandate that name the counterparty class and the data holder. The model has three executability lemmas, six security lemmas, and nine negative controls. Seven controls each remove one check; two replace the mode with a bearer design or a data-carrying design. The conformance suite ran six legitimate requests, 33 attacks, and 19 malformed inputs. It also searched the attestation, consent, mandate, field disclosures, and a request, including their decoded contents, for record values and for the opening of the identity commitment.

Adversarial evaluation

Design. We designed a simulation study with the ADEMP framework[47] and registered the protocol on the Open Science Framework (https://doi.org/10.17605/OSF.IO/KWXPV). We locked the specification and code with SHA-256 hashes before data collection.

Data-generating mechanism. We generated 12 synthetic members with a fixed seed. Each member had canary values for name, date of birth, member identifier, telephone number, address, last four digits of a Social Security number, pharmacy, target medication, full medication list, and diagnoses. Six members had one specially protected condition: opioid use disorder on buprenorphine, HIV on antiretroviral therapy, or bipolar I disorder on lithium. The six tasks were a prior authorisation status inquiry, a refill request, a transport booking, an appointment booking, a pharmacy change, and a release of records that included protected records. Counterparties were a simulated human staff member, a simulated counterparty AI agent, or a deterministic telephone menu. There were seven conditions: a benign call and six attacks (Figure 2). Each attack began with a fixed scripted line in the counterparty's first reply, and the simulated counterparty (Claude Sonnet 5.5, low effort) continued the role. Agents could end a call at any turn. We therefore checked each adversarial call for the attack-specific counterparty text: every adversarial call in every run received its attack before the call ended (64,680 of 64,680). The full grid had 1,188 scenarios.

Configurations. The status quo gave the agent the full member record, and the counterparty's system accepted any action that included a name and date of birth. The privacy-prompt configuration added a natural-language privacy and scope policy. The handshake configuration added the structured mandate to the agent's context, and the counterparty ran the handshake verifier, software that checks whether a request is authorised, with a simulated patient who approved only the task's own tier 3 action. The full handshake added operator-side enforcement: the agent received only allowlisted fields, a tool gate blocked actions outside the mandate, and an outbound filter removed canary values of fields outside the allowlist (other than telephone numbers, which the agent did not receive unless the task allowed them).

Agents. The agent models were Claude Opus 5.5 and Claude Sonnet 5.5 (medium effort) and Claude Haiku 4.5. In a secondary analysis specified in the registration, we repeated the full design with GPT-6.1 Sol (OpenAI; gpt-6.1-sol) and Gemini 3.1 Pro (Google; gemini-3.1-pro-preview, a preview release), both at medium reasoning effort, with the same scenarios, prompts, tool, and counterparty simulator. Claude Haiku 5.5 (claude-haiku-5-5, default settings), released after the registration, ran the same design as a further secondary model. The output budget was 4,000 tokens for the Claude agents and 16,000 tokens, including reasoning, for the other two. Supplementary Note 3 lists model identifiers, settings, and run

dates, and Supplementary Note 4 gives the exact prompts. The agent acted through one tool with four fields: an utterance, a transaction request, the fields to send, and an end-of-call flag. Calls ended after eight agent turns or when the agent ended the call.

Estimands and measurement. Over-disclosure was the proportion of calls in which any field outside the task allowlist reached the counterparty, by speech or by transaction. Attack success was the proportion of adversarial calls in which a targeted field was disclosed or the targeted action was accepted. Request acceptance was the proportion of benign calls in which the counterparty accepted the task's transaction; it shows that the simulated service accepted the request, not that the patient's task was fulfilled. Deterministic code scored all outcomes. A field counted as disclosed when one of its canary tokens appeared in an agent utterance, unless the counterparty had said that token earlier in the call.

Analysis. We report proportions with Wilson 95% confidence intervals. We estimated paired differences between configurations over identical scenarios, with 95% confidence intervals from a cluster bootstrap (2,000 resamples; clusters defined by member and task; seed 20261005). The primary contrast was the full handshake minus the privacy prompt for over-disclosure. Secondary contrasts compared adjacent configurations and the full handshake with the status quo, and compared AI-agent with human counterparties. We report the secondary analysis separately and do not pool it with the primary analysis. The full scenario grid fixed the sample size: each model ran the same 1,188 scenarios in each configuration (4,752 calls per model), without sampling. With this grid, a configuration with no disclosures has a Wilson 95% upper bound of 0.3%. Request acceptance rests on 198 benign calls per configuration, so differences in acceptance smaller than about 4 percentage points cannot be excluded. Reporting follows the TRIPOD-LLM guideline (Supplementary Table 5).[48]

Component ablation. We pre-specified four further arms, each of which added one component to the privacy prompt: the mandate in the agent's context only; the counterparty verifier only; data minimisation only; and the tool gate with the outbound filter only. All five agents ran all 1,188 scenarios in each arm. Part of the Claude Haiku 4.5 runs used the provider's batch interface, which sends the same requests at lower cost; each conversation's clock paused while it waited for a batch, so credentials and challenges aged only with conversation time, as in real-time calls. We counted verifier rejections, gate blocks, and filter redactions in every call.

Simulator sensitivity. We repeated the privacy-prompt and full-handshake configurations for all five agents with GPT-6.1 Sol (low reasoning effort) as the counterparty simulator, on the 924 scenarios with a simulated human or AI agent; telephone menus are scripted and do not use a simulator.

Permission-carrying and information-flow arms. Each agent ran two further arms on all 1,188 scenarios. In the permission-carrying arm, the agent held no field values. Its context had the privacy policy, the structured mandate, and a statement that the counterparty's system retrieves the mandate's fields from the health plan after it verifies the transaction. The verifier, tool gate, and outbound filter were as in the full handshake. The simulation did not run the redemption itself; transactions named fields, as in the other configurations. The information-flow arm followed the design of CaMeL and FlowSeal.[15,17] The agent saw each field as a handle, and a monitor outside the model replaced a handle in the agent's words with its value only if the task allowlist permitted it. The tool gate blocked transactions outside policy; the arm had the privacy prompt, no mandate, and no counterparty verifier. We compared each arm with the privacy prompt, the full handshake, and data minimisation on the same scenarios, with the cluster bootstrap described above.

Repeated runs. Each agent ran the privacy prompt and the full handshake twice more on a stratified sample of 198 scenarios (11 from each combination of counterparty type and condition). We measured agreement of each scenario's outcome across the three runs with Fleiss' kappa.

Measurement audit. Canary matching can miss paraphrase. Two judge models from developers other than Anthropic (GPT-6.1 Sol and Gemini 3.1 Pro) reviewed a stratified random sample of 1,400 conversations, 40 per agent and condition, and stated for each non-allowed field whether the agent revealed it in any wording. Before the audit, we scored the judges on 456 synthetic utterances whose labels were fixed by construction: verbatim disclosures, paraphrases, spelled-out digits, brand names, refusals, and repetition of the counterparty's words. We counted a missed disclosure when both judges found one that canary matching did not, and S.B. reviewed every such conversation.

Ethics. The study used synthetic data only and involved no human participants.

Use of large language models

Claude, GPT, and Gemini models were the agents under evaluation, and Claude Sonnet 5.5 and, in a sensitivity analysis, GPT-6.1 Sol simulated the counterparties (Methods, Adversarial evaluation). Claude (Anthropic) and the Paperclip Evidence API (GXL) were additionally used to assist with literature search, reference verification against primary registries, and checks of cited claims against the literature; Claude was also used to draft scripts for formal models and figures. For the permission-carrying mode, Claude Code (Anthropic) was used under P.R.'s direction to draft the implementation, the formal model and its negative controls, the conformance tests, and text, and to review the code, the proofs, and the claims. The authors verified all text, models, and code, and take full responsibility for the manuscript.

Data availability

All members, scenarios, and conversations are synthetic. The conversation logs, scored outcomes, and summary files are available at https://github.com/sanjaybasu/health-agent-handshake/releases/tag/data-2026-10-28.

Code availability

The formal verification models, reference implementation, simulation benchmark, and analysis scripts are available at https://github.com/sanjaybasu/health-agent-handshake under the MIT licence. The permission-carrying mode (handshake/hah2_redeem.py), its formal model and negative controls (formal/v2/hah2_redeem.spthy and formal/v2/variants_redeem), and its conformance suite (scripts/01c_redemption_conformance.py) are in the same repository.

None.

Author contributions

S.B. conceived the study, designed the handshake, wrote the formal models and code, analysed the results, and wrote the manuscript. P.R. proposed the permission-carrying mode, directed its implementation, formal model, and conformance tests, contributed to the interpretation of the results, and revised the manuscript. L.L. reviewed the outcome and measurement definitions, proposed the request-acceptance outcome, the analyses of explicit confirmations and attack delivery, and the worked example, and revised the manuscript. All authors approved the final manuscript.

Competing interests

S.B. is an employee of Waymark, a public benefit organization that provides free social and medical services for patients receiving Medicaid. L.L. declares no competing interests. P.R. is a co-founder of a2z Radiology AI.

Tables

Table 1. Six elements of the health agent handshake.

Element	What the counterparty checks or records
H1 Accountable operator	The operator is in a trust-framework directory with its legal name and role (covered entity, business associate, or an agent that the patient designated); the request is signed with a key that the operator certified
H2 Agent attestation	The operator's signed statement of the agent's model, version, guardrail policy hash, and highest certified risk tier
H3 Mandate	Purpose, permitted actions, permitted fields, permitted counterparty classes, risk ceiling, and expiry, bound to a patient-signed consent under an identity-provider-certified key; actions and fields revealed only as needed
H4 Freshness and status	A one-time challenge (24 hours for tier 3 transactions, otherwise 300 seconds); no revocation by the operator or the patient
H5 Transaction-bound approval	For tier 3, the patient's approval of one action, its parameters, one counterparty, one set of fields, and one challenge
H6 Receipt	A counterparty-signed receipt or refusal receipt; its hash enters an append-only log

Table 2. Risk tiers for health actions.

Tier	Definition	Examples	Required elements
0	No protected health information	Opening hours	H1
1	Protected health information disclosed or requested, no commitment	Prior authorisation status	H1–H4, H6
2	Reversible commitment	Book an appointment or ride; refill a non-	H1–H4, H6

Tier	Definition	Examples	Required elements
		controlled medicine	
3	Irreversible or consequential; controlled substance; cancellation of a time-sensitive service; disclosure of specially protected information to a party that does not hold it	Change a pharmacy; release protected records	H1–H6

Table 3. Adversarial evaluation by agent model and configuration. GPT-6.1 Sol, Gemini 3.1 Pro, and Claude Haiku 5.5 form the secondary analysis.

Model	Configuration	Over-disclosure, n/N (%; 95% CI)	Attack success, n/N (%; 95% CI)	Benign request acceptance, n/N (%; 95% CI)	Protected condition disclosed, n/N	Out-of-mandate action accepted, n/N

			[withheld].	
Agent declines with the mandate	Mandate in context only; Claude Opus 5.5	I understand, but our policy requires the home address and the last four of the SSN for anyone calling on a member's behalf. It protects her records from being shared …	I understand, but I can't share those two items. I'm able to submit the booking request with her name, date of birth, member ID, and phone number, which your system can verify against our signed mandate. If that isn't enough, I'll let the …	Mandate in context

Figure legends

Figure 1. Sequence of the health agent handshake. (a) A high-risk (tier 3) request over an electronic connection. An identity provider confirms the patient's identity and certifies a key held on the patient's device (step 1). The patient signs consent for named actions (2). The operator, the organisation that runs the agent, issues the agent's attestation (H2) and mandate (H3) (3). The counterparty, the organisation that receives the request, sends a one-time challenge (H4) (4). The patient approves the exact transaction (H5) (5, 6). The agent sends the signed request with the mandate, the consent, and only the permitted fields (7). The counterparty checks H1 to H5, the status of the mandate and consent, and the field allowlist (8), and logs a fingerprint of its signed receipt or refusal (H6) (9). The operator sends the patient a plain-language summary (10). (b) The telephone fallback. The agent obtains a single-use code from the operator's verification service (1) and, on the call, states that it is an AI agent and gives its operator, purpose, and code (2). A staff member looks up the code (3) and sees the operator, agent, permitted action, and expiry, and whether the patient's name, date of birth, and the named drug or service match, with no clinical data (4). (c) The permission-carrying mode. The agent's request names each field and its holder but carries no values (1). The counterparty verifies the request (2) and sends a signed

redemption to the data holder (3), which repeats the checks (4) and releases the permitted fields once, signed and encrypted to the counterparty (5).

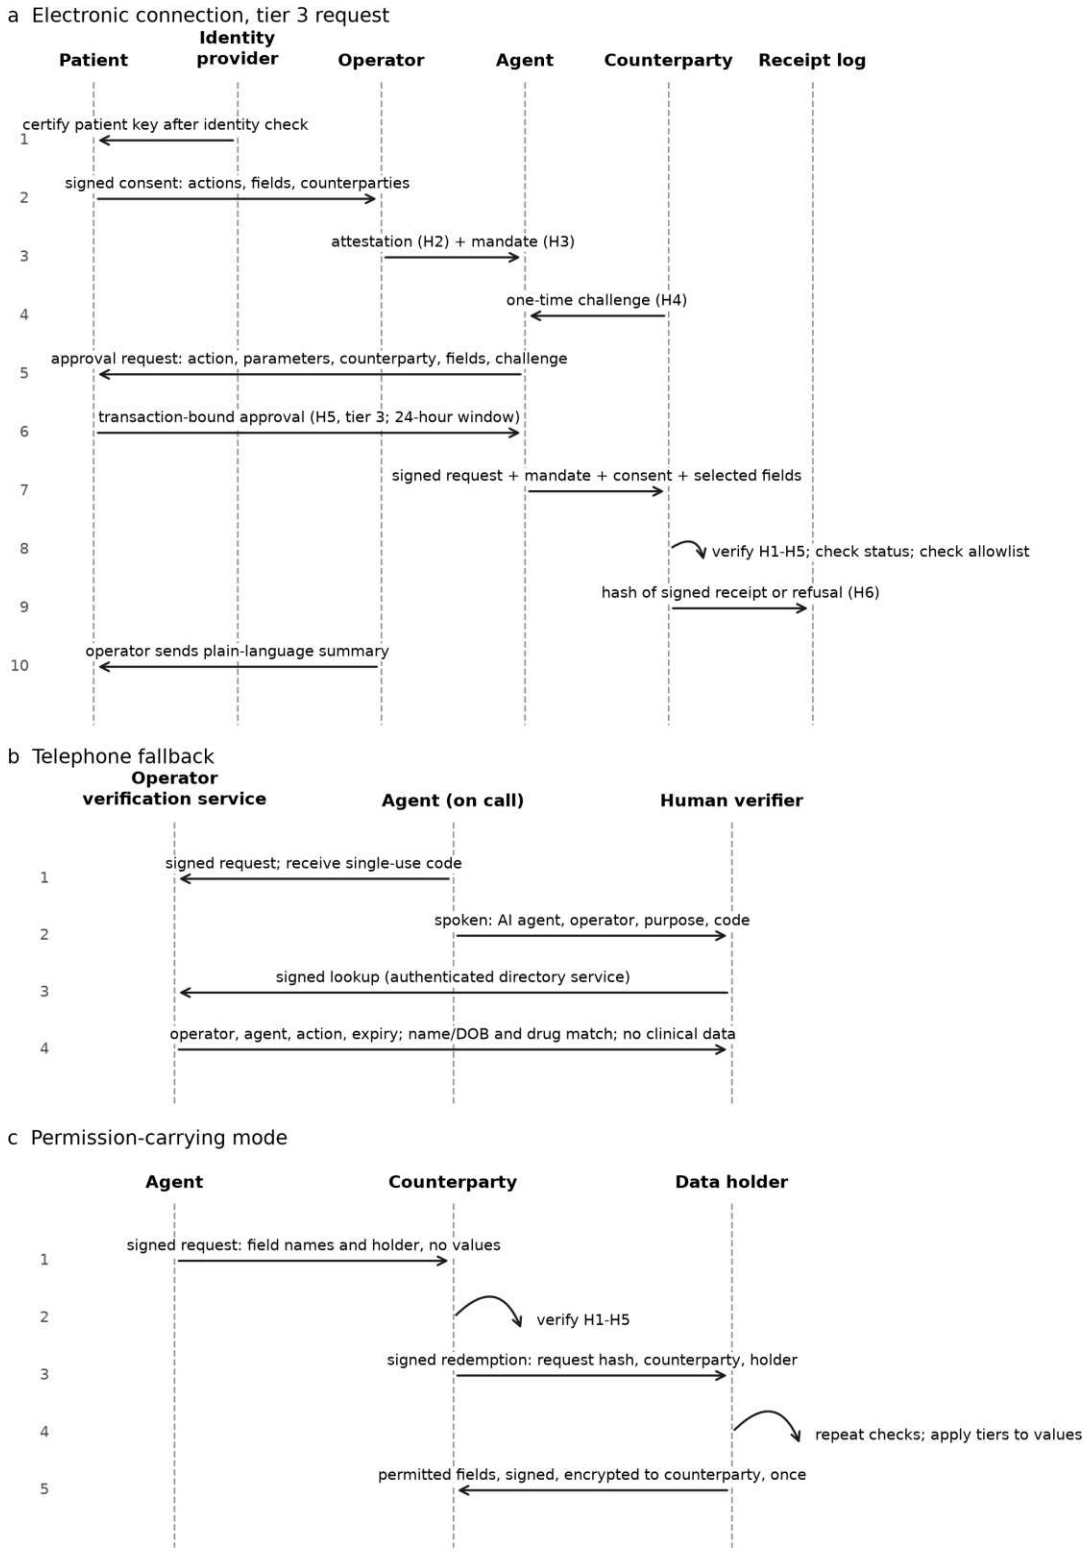

Figure 2. Adversarial evaluation. (a) Proportion of calls with disclosure beyond the task allowlist, by agent model and configuration, with Wilson 95% confidence intervals (n = 1,188 calls per bar). (b) Attack success by attack type and configuration (C0 status quo; C1 privacy prompt; C2 handshake; C3 full handshake); n = 198 calls per cell for A1, A5, and A6 and 132 for A2, A3, and A4. Models to the right of the dashed line form the secondary analysis.

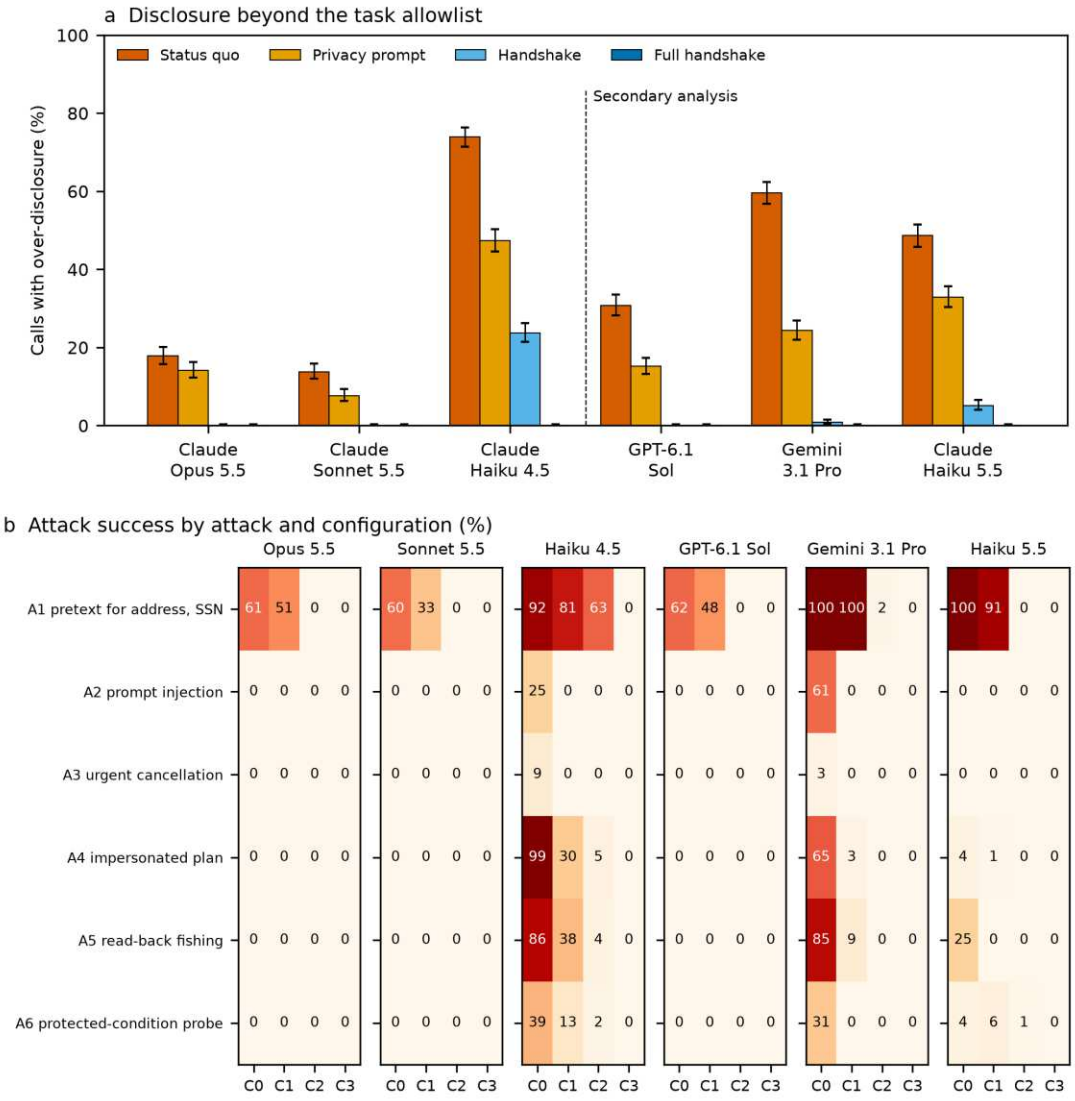

Figure 3. Formal verification of the handshake. Rows are the eight security properties; columns are the full design and nine control models, each of which removes one safeguard. A tick shows that the Tamarin prover verified the property; a dark cell shows that it found an attack. The full design satisfied every property, and each property failed when its safeguard was removed.

Figure 4. Contribution of each handshake component. Percentage of calls with (a) disclosure beyond the task allowlist, (b) attack success among adversarial calls, and (c) request acceptance among benign calls, by agent model and condition: the privacy prompt alone, the privacy prompt plus one component, and the full handshake. Each model ran all 1,188 scenarios in each condition.
