Abstract

**Background:** This study systematically reviews and Meta-analyses the best-published evidence on the therapeutic value of strengthening hip abductors and lateral rotators muscles for the treatment of Patellofemoral Pain (PFP) with a presumptive hypothesis that strengthening hip muscles stabilises the patellofemoral joint, relieves pain and enhances knee functions.

**Methodology:** Electronic database searches of Medline, EMBASE, CINAHL, PEDro and PubMed Central between January 1994 and September 2019 using PICO5 tool. The methodological quality of the selected studies was appraised individually using the 20-item McMaster Critical Review Form for Quantitative Studies. Supplemental quality appraisal of randomized controlled clinical trials performed using the Cochrane Collaboration's 'Risk of bias' quality criteria. Data on patient population demographics, interventions, duration of intervention and outcome measures were extracted, summarized in evidence tables and descriptive analysis made. Pooled effects size from appropriate RCTs was determined by meta-analysis under both fixed and random-effects models.

**Results:** All included fourteen studies demonstrated that hip muscles strengthening resulted in improved pain and knee function. All RCTs, except one, demonstrated that hip muscles strengthening is superior to quadriceps strengthening. Of the five RCTs accessing the surplus effect of hip-quad versus quadriceps strengthening, four suggested that hip-quad strengthening is superior over the standard quadriceps strengthening alone to improve PFP and knee function.

**Conclusion and Implications:** In patients with PFP, strengthening of hip abductors and lateral rotators have greater therapeutic significance than the conventional quadriceps exercises in improving knee pain and function both in the short- and long term. However, caution is required, because a standardized hip-quad protocol is yet to be developed, which warrants further studies.

**Systematic review registration:**

There was no protocol prepared and no amendments were present. This systematic review is registered under Open Science framework, with following registration digital object identifier 10.17605/OSF.IO/CWZ8V

Introduction

Patellofemoral pain (PFP) is characterised by anterior knee pain emanating from the patellofemoral joint involving patella and fibrous tissue on the medio-lateral retinaculum [1]. The aetiology is irregular patellar kinematics due to excessive pressure on the patellofemoral joint coupled with poor proximal neuromuscular control and hip muscle weakness [2–4]. The pain in PFP is because of inflammation coupled with damage to bony, cartilaginous or the connective tissues of the patellofemoral joint [1, 2, 5].

The PFP incidence rate is 25–40 % of all cases of anterior knee pain which is considerably high. Hence, therapeutic interventions are imperative to reduce permanent knee disabilities and improve quality of life [5–7]. The prevalence of PFP is higher in women and athletes than males (2:1) and is even higher (4:1) among athletes [6].

The works of literature on musculoskeletal injuries indicate a positive correlation between hip muscles weakness and PFP [8–10]. In a case report on PFP, authors noted that excessive hip adduction coupled with the weakness of the hip extensors and abductors are predominantly musculoskeletal concerns [10]. The current physiotherapy evidence strongly supports quadriceps muscle strengthening as an effective strategy to improve overall knee function in patients with PFP [11–13]. The proximal hip muscles exercises reported to be effective in relieving patellofemoral pain and improving knee function when compared to knee exercises alone [14]. Therefore, strengthening these muscles underlies the objective treatment of PFP. While quadriceps strengthening is already the standard physiotherapeutic target for PFP, it is plausible that strengthening of hip muscles will serve greater benefits, because of its effect on greater control over the knee biomechanics [5, 15].

Relationship between Hip Muscles (abductors and external rotators) Strength and PFP

Muscles of the hip (hip abductors and external rotators) are essential for knee and pelvic stabilization during ambulation [5]. The hip abductors and external rotators act synergistically to eccentrically control the hip adduction and internal rotation movements, respectively [15–17]. The diminished strength of hip abductors and external rotators muscles may result in poor neuromuscular control during activities that necessitate loading on the patellofemoral joint [5, 8, 18]. The weak hip abductors may cause excessive femoral adduction, thereby, augmenting lateral forces (Knee Valgum) acting on the patella [19]; while, weak hip external rotators results in unrestricted internal rotation of the femur, that augments contact pressure between the lateral facet of the patella and lateral femoral condyle [19]. Hence, weak hip muscles (mainly hip abductors and external rotators) is an important aetiologial factor for PFP [5, 15, 20, 21].

Many studies compared the effectiveness of hip muscles strength in patients with PFP to matched healthy controls [16, 21–23]. Ireland et al. reported eccentric muscle strength reduction of 26% in hip abductors and 36% in hip external rotators among females with PFP while Souza & Powers, found a reduction of 14% in hip abductors and 17% in hip external rotators eccentric muscle strength compared to healthy matched
controls [16, 21]. Nevertheless, Piva et al. found no significant muscle strength differences for hip abductors and external rotators in patients with PFP compared to healthy age/gender-matched controls; however, Baldon et al. reported significantly reduced strength for eccentric hip abductors, but not for hip external rotators among females with PFP to healthy matched controls [22, 23].

The weak hip lateral rotators cause unrestricted internal rotation of the femur about the tibia, enhancing misalignment at the knee joint that in turn leads to a biomechanical imbalance between the hip extensors and lateral rotators, that overloads the retinaculum and subchondral bone and subsequently potentiate patellofemoral pain and knee dysfunction [21]. Nevertheless, Earl et al. opined that strong hip muscles (abductors and external rotators) reverses these effects over the knee joint [3].

Ireland et al. and Souza & Powers noted more weakness in hip external rotators compared to hip abductors in patients with PFP[16] [21]. Ferber et al. found that in patients with PPS, the three weeks of isolated hip abductors strengthening not only reduces patellofemoral pain but also increases gait-related knee-joint stability [9]. Two recent randomised controlled trials found that isolated strengthening of hip abductors and external rotators effectively relieves pain and improvise knee function in females [4, 17]. The available pieces of evidence for PFP considered exercises to strengthen the hip muscles that reduces pain and enhances long-term knee function [3, 4, 6, 17, 24].

**Outcome Measures of Pain, Knee Function and Health Status in PFP:**

The available studies used self-reported Kujala Anterior Knee Pain Scale (AKPS), Visual Analogue Pain (VAS) scale, 11-point Numerical Pain Rating Scale (NPRS) and Pain Severity Scale (PSS) as an outcome measure to document patellofemoral pain in patients with PFP receiving therapeutic interventions [14, 25, 26].

The knee functions for patellofemoral pain were assessed using the Lower Extremity Functional Scale (LEFS), Tegner Activity Scale (TAS), Lysholm Knee Scoring Scale (LKSC)/ Tegner Lysholm Knee Scoring Scale (TLKSS), Knee Outcome Survey-Activities of Daily Living Scale (KOS-ADL) and Functional Index Questionnaire (FIQ) [26–30].

Though, the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) is tailored to examine the functional status of osteoarthritis, is also been used to measure health status for patients with patellofemoral pain [because patients with osteoarthritis often present with anterior knee pain which is similar to patellofemoral pain] [25].

Since, systematic reviews evaluating the effect of hip abductors and lateral rotators strengthening for patellofemoral pain, knee function and quality of life in patients with PFP are extremely limited, even though, evidence indicating the presence of weak hip abductors and external rotators. Primarily this study systematically reviews and Meta-analyses the best-published evidence on the therapeutic value of strengthening hip abductors and lateral rotators muscles for the treatment of PFP. This is being guided by the presumptive hypothesis that strengthening hip muscles stabilises the patellofemoral joint, relieves pain and enhances knee functions.

**Methodology**

**Justification of the Systematic Review Approach**

Systematic reviews and meta-analyses are important methodologies for the qualitative and quantitative synthesis of published evidence. Shreds of evidence presented in systematic reviews are key for continuous quality and safety improvements in evidence-based clinical practice and therefore, useful for both clinicians and healthcare policymakers. The present review study used Centre for Reviews and Dissemination (CRD) guidance for undertaking reviews in health interventions to assess the value of hip muscles strengthening as therapeutic interventions in patellofemoral pain and knee function in patients with PFP [31]. Additionally, the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement, recommended in CRD's guidance is used in literature searches to minimise biases in article selection and reporting [32]. The review has been registered with Open Science framework with reference doi: 10.17605/OSF.IO/CWZ8V

**Electronic bibliographic database searches**

The controlled clinical trials (randomised and non-randomised), controlled comparative studies and cohort studies ((prospective and retrospective) published in the last 25 years (January 1994 to September 2019) in English language journals were performed across five electronic databases [Medical Literature Analysis and Retrieval System Online (Medline); Excerpta Medica Database (EMBASE); Clinical Index of Nursing and Allied Health Literature (CINAHL); Physiotherapy Evidence Database (PEDro) and The Cochrane Central Register of Controlled Trials (CENTRAL)]. Appropriate combinations of Medical Subject Headings (MeSH) or CINAHL headings with keywords (Table 1) using Boolean Operators (AND, OR & NOT) along with PICOS (target population, intervention, comparator, outcomes and study design) were used [33].

Additional electronic searches are done in the Meta register of Controlled Trials (mRCT) via the Current Controlled Trials (CCT) database to locate ongoing RCTs with potentially relevant data useful for the present systematic review. The potentially relevant clinical controlled trials and cohort studies (otherwise not indexed in any of the five electronic bibliographic databases and mRCT), electronic searches were supplemented by
searching unpublished papers from the OpenGrey (formerly SIGLE) database. The literature searches were additionally supplemented with manual bibliographic searches of relevant systematic reviews, editorials and thesis reports published by the digital libraries of the University of Manchester, University of Central Lancashire and Australian Digital Thesis programmes including ProQuest. Authors of potentially relevant unpublished reports were contacted by e-mails seeking clarification of their respective studies with the possibility of inclusion in the present review.

Study Selection

The study selection performed by the PRISMA flow chart where returned hits for each electronic bibliographic database were screened initially based on title and abstracts. The number of potentially relevant articles were noted and citations imported into Endnote citation manager (EndNote X7), and full-text articles retrieved for further eligibility screening. Studies were included based on the following criteria:

Inclusion criteria

1. Studies that enrolled adolescents (≥14 to ≤19 years) and/or adults (≥50 years);
2. Studies involving patients with the confirmed clinical diagnosis of patellofemoral pain presented with anterior or retro patellar knee pain during physical activities i.e. running, climbing staircase, squatting, hopping, and kneeling or prolonged sitting;
3. Studies involving patients diagnosed with patellofemoral pain without underlying knee pathologies (e.g. Osteoarthritis), previous knee trauma or surgery;
4. Only controlled clinical trials (RCTs, Non-RCTs, and comparative studies) and cohort studies assessing the effect of hip abductors and/or external rotators strengthening on pain and functional outcomes of patients with a confirmed diagnosis of patellofemoral pain;
5. Studies published as books, chapters or conference abstracts or interim results in the mRCT database provided that authors were contacted successfully;
6. Studies comparing strengthening of hip abductors and/or external rotators muscles with standard quadriceps strengthening or no exercises;
7. Studies where the intervention group received hip muscles strengthening exercises coupled with quadriceps strengthening provided that the comparator group received only the quadriceps strengthening protocol;
8. Studies measuring pain by VAS, AKPS, 11-point NPRS, PSS, and functional outcomes examined on TAS, LKSS, FIQ, TLKSS LEFS, PFJES, or WOMAC instruments;
9. Studies published in English only were included for the review.

Exclusion criteria

1. Studies that were not quantitative such as reviews, editorials, commentaries, which merely reviewed the physiotherapeutic benefits of hip muscles strengthening to patients with patellofemoral pain;
2. Studies published more than 20 years ago;
3. Studies that recruited PFP patients with other underlying knee pathologies such as knee osteoarthritis, knee cartilaginous injuries, meniscal tears or knee surgery;
4. Studies that included the non-exercise co-interventions such as electro-muscular stimulation (electrotherapy), patella taping, and orthotics;
5. Studies reported neither patient pain nor functions.

Critical Appraisal of Methodological Quality

The McMaster Critical Review Form for Quantitative Studies applied to examine the methodological quality of all selected studies for study’s objectives, literature survey, study design, sample population, intervention, outcome measures, results, significance, limitations, and conclusions (Table 2) [14]. Knowing that biases are the main threats to the internal and external validity of RCTs, quality appraisal of RCTs performed using The Cochrane Collaboration's 'Risk of bias' tool tailored specifically for RCTs [34]. The risk of patient selection bias was examined for the selected RCTs for the sufficiency of random sequence generation and concealment allocation to interventional and control groups. This helped to determine the comparability of the study groups at baseline. The risk of performance bias was evaluated based on measures (such as single blinding or double-blinding) employed to ensure study participants and personnel are blinded to interventions and outcomes. The risk of detection bias was assessed to know if the assessors were adequately blinded to patient group allocation. The risk of attrition bias and the risk of incorporation bias examined based on the rate and pattern of the dropout of participants, handling of incomplete outcome data and the indications of intention-to-treat (ITT) analysis. Finally, the risk of reporting bias evaluated based on the possibility of selective outcome reporting. The reproducibility of exercise therapies prescribed, confounding/modifying effects of co-interventions and the levels of supervision and patient compliance to the prescribed physiotherapy during the trial were also evaluated across the RCTs studies.

Data Extraction and Qualitative Synthesis
Data on effect measures were extracted for baseline patellofemoral pain levels, hip exercise interventions, including the comparator treatment, quantitative assessment of patient outcomes for patellofemoral pain and functions, follow-up duration and post-intervention practices during the follow-up periods. Statistical results (mean differences from baseline and effect measures \( P \) value at 95% confidence interval) were taken from the evidence tables for interventional studies (separately for controlled clinical trials and cohort studies).

Quantitative Synthesis (Meta-Analysis)

Using MedCalc software (Version 14.10.2, MedCalc Software Ltd), data from RCTs that provided the mean difference of pain or knee function between the intervention and the comparator groups were pooled by random or fixed-effect models to obtain standardised mean differences. Separate forest plots were generated for pain and knee function outcome.

Results

The primary electronic searches in the five bibliographic databases using the PICOS search strategy returned 114 potentially relevant citations. Through careful screening for duplicates based on titles and authors, 50 citations were excluded. The 43 articles were excluded after careful screening of titles and abstracts from the remaining 64 articles because they were not irrelevant. The full texts of the remaining 21 articles were evaluated rigorously for eligibility based on the inclusion and exclusion criteria, and through this process, 10 studies were excluded because of the following reasons;

1. Six articles excluded because they involved patients with knee osteoarthritis or mixed participants with PFP and osteoarthritis,
2. Two studies excluded because they focused on hip/quadriceps muscle strengths as the only outcome measure after interventions without assessing pain or functional outcomes,
3. One study appeared relevant, but lacked the description of exercise interventions administered,
4. Lastly, one study contained duplicate experimental data from another included original study.

Three potentially relevant studies were identified through manual bibliographic hand searches of three recent systematic reviews [14,35,36]. The complete process yielded 14 studies. Among these, 10 were controlled clinical trials (CCTs), and 3 were cohort studies while 1 was a case series [3,4,6,9,17,24,37–44]. The 3 cohort studies met the inclusion criteria for qualitative synthesis. Nine controlled clinical trials were true randomised controlled trials (RCTs) presenting data suitable for quantitative synthesis (meta-analysis) [4,6,17,24,37–39,41,42]. The literature search strategy and article selection process are summarised in the PRISMA flow chart (Fig. 1) [32].

Controlled Clinical Trials

A total of 383 participants from the 10 CCTs received either hip-strengthening exercises (N=74) or quadriceps strengthening exercises (N=157) or hip/quadriceps strengthening exercises (N=108) or no exercise (N=44) (Table 2). All CCTs involved true randomization of participants except one, where participants were allocated to their respective groups alternately in a consecutive manner [40].

Intervention Protocol:

In all CCTs, the hip muscles strengthening protocol focused on hip abductors and lateral rotators. The hip exercise protocol included hip abduction against an elastic band while standing, or with weights in side-lying position coupled with hip lateral rotation against an elastic band while seated and hip extension; quadriceps strengthening involved closed kinetic chain exercise or seated knee extension, leg press, squatting and stretching of hamstrings and quadriceps; and, hip-quadriceps strengthening involved combination of the hip-quadriceps protocol. The duration of intervention ranged from 3- 8 weeks, while the frequency of therapy sessions ranged from 2-4 per week (Table 3).

Outcome measures

All CCTs examined both pain and functional outcomes except one, which assessed only pain [41]. The pain was commonly evaluated using 10-cm VAS by all CCTs except two, which used the 11-point NPRS [4,24]. The pain was evaluated during ascending and descending stairs [4,24,41], squatting, usual pain [41], and worst knee pain in the previous week [6,17,39–42]. Functional outcomes were assessed using LEFS [4,6,24,38], AKPS [4,6,24,39], PFJES [37], TLKSS [42] and WOMAC [17,40].

Follow-up duration

Post-intervention measures were immediately carried out at the end of the intervention period in all studies. However, the post-interventional follow-up period ranged from one to twelve months (Table 4).

Critical appraisal
Methodological quality assessment of the 10 CCTs based on the Cochrane Collaboration's 'Risk of bias' tool tailored for RCTs is detailed in Table 5 & 6 below [34].

I. Cohort and Case Series Studies

The three cohort studies had 88 participants [PFP (n=64); healthy controls (n=24)]. The one case series involved 19 participants with PFP.

**Intervention Protocol:**

In one cohort study, the experimental group given hip muscles exercise protocol (strengthening of hip abductors and external rotators), and the control group received knee exercises. The other two cohort studies subjects received quadriceps- strengthening [43,44]. The duration of intervention ranged between three to six weeks. The case series participants completed an eight-week exercise programme focusing on hip muscles strengthening and improving dynamic misalignment (Table 7).

II. Meta-analysis (pooled effect size)

The meta-analysis was done to determine the additional effect of hip muscles strengthening as adjunctive therapy to the standard quadriceps strengthening for PFP and knee function.

A. The comparative effect size of Hip versus Quadriceps strengthening on pain and function

Two RCTs [6,38] and one comparative control trial [40] provided data that compared the effect of the isolated strengthening of hip muscles (hip abductors and lateral rotators) versus the standard quadriceps strengthening on PFP and knee function. A total of 100 participants were randomly assigned to receive either hip (n=50) or quadriceps (n=50) strengthening protocols. The standardised mean difference (SMD) of PFP and functional outcomes after intervention with 95% CI under both fixed and random effects models favoured hip muscles strengthening over quadriceps strengthening (p<0.001) (Fig. 2 and 3).

B. Surplus effect of hip-quad versus quadriceps strengthening on pain and function

Five RCTs contributed data assessing the surplus effect of hip muscles strengthening coupled with quadriceps strengthening compared to the standard quadriceps strengthening alone on PFP and knee function [4,24,39,41,42]. For both the group (hip-quad and quadriceps alone), 16 data sets were collected from a total of 98 participants. The pooled effects of results are presented in forest plots Fig. 4 and 5 as cumulative SMD with 95% CI, under both fixed and random-effects models.

**Discussion**

Two recent systematic reviews have demonstrated that proximal exercises targeting quadriceps and hip muscles strengthening were effective in relieving pain and improving knee function in patients with PFP, both the short- and long-term [14,36]. However, this systematic review was important to delineate the effect of the isolated strengthening of hip abductors and lateral rotators on pain and knee function in patients with PFP compared to non-exercise interventions and to identify if hip muscles strengthening is superior over the quadriceps strengthening alone among them.

**A. Quality of the Summarised Evidence**

The methodological quality of the fourteen studies except five i.e. [6,9,37,43,44] included in the present review is excellent because it fulfilled 14 of the 16-item McMaster critical review criteria. The common methodological issue observed in the majority of the selected studies was lack of sample size justification (sample size not determined or not achieved) [6,17,37,39,40,43]. All studies with sample power inadequacy issue, achieved results with statistical significance, suggesting that the measured pain and functional outcomes reflect the comparative effect of the interventions. However, subject contamination in Dolak et al. was evident because hip and quadriceps groups were combined as one to receive functional strengthening exercises (as co-interventions for the last four weeks of the intervention) [6]. Such subject contamination might have caused patient bias for their pain and functional outcomes, especially if they know the intervention of their cohorts in the opposite arm of the study [45].

This risk of bias is a critical methodological issue in RCTs and warranted supplementary quality appraisal of all RCTs on the Cochrane Collaboration's 'Risk of bias tool' [34] to highlight methodological flaws (indicative of 'Risk of bias' threatening interval consistency) (Table 6). All RCTs except two recruited participants with a confirmed diagnosis of PFP [17,40]. However, these studies were included because they enrolled patients presented with anterior knee pain based on symptoms matching the inclusion criteria of the remaining RCTs, which recruited patients with a confirmed diagnosis of PFP. Here, 383 participants from all RCTs presented with anterior knee pain associated with prolonged sitting, climbing stairs and descending stairs in the absence of signs/symptoms of meniscal or other intra-articular pathological conditions, or history of
other knee pathologies, surgeries and injuries. These are classical symptoms for the diagnosis of PFP [14,36]. However, these symptoms may be indicative of knee osteoarthritis, but it may not be so likely because patients enrolled in RCTs were not older than 50 years of age, and therefore not likely to present with ageing-associated PFP [46].

Four studies included the mixed population of both adults and adolescents aged 17 to 50 years [6,38,39,41]. Since adolescents are physically active, therefore, at risk of PFP hence, the inclusion of this age group [46]. To minimise the possibility of recruiting participants with underlying knee pathologies i.e. knee osteoarthritis, no studies recruited patients with PFP who were older than 50 years of age [46]. The four studies examined only female participants, therefore, the outcome may only be generalised for the female patients with PFP; but not for the males [4,6,24,38]. The three studies [39,41,42], included both males and female participants (proportion of females was higher than males), indicative of females being the greater risk of PFP than males [6]. This may be attributed to the lower hip muscle mass in females compared to males [47], therefore, females exhibiting lower hip muscle strength than males [47,48].

The symptom duration is a direct measure of severity of PFP that has a significant influence on therapeutic outcome [49]. Therefore, patients with early diagnosis of PFP likely to respond well to therapy compared to those with late diagnosis [20]. Thus, symptom duration is a key confounding variable that needs to be adjusted via the subject's stratification. In this systematic review, the mean duration of symptoms of participants with PFP in eight studies ranged from 17 to 21 months. However, six studies [17,37–41] did not report the mean duration (months) of PFP symptoms. None of the studies performed the subject's stratification for the PFP severity and symptom duration. This might have positively skewed pain and functional outcomes in patients with a shorter mean duration of symptoms [20]. Additionally, the subject's characteristics were barely explained in three studies [38,40,41] and also not detailed in one study [37]. These findings undermine the quality of the summarised shreds of evidence.

Supervised therapeutic exercises enhance participant's compliance because unsupervised participants may refrain from pain-provoking exercises [20,50]. Two previous RCTs had reported that supervised exercises for PFP result in less pain and better knee function at short- and long-term follow-up compared to usual care [20,50]. In the present systematic review, all studies involved exercises administered in physiotherapy facility/rehabilitation setting under supervision by qualified physiotherapists, except two [6,41], where two-thirds of exercise sessions were self-administered in patients homes (unsupervised), while one-third had at rehabilitation facility under supervision. It had an important bearing on patient compliance to intervention and the outcome. Even then, results were significant in these two studies suggesting that partial supervision too can yield clinically significant results.

**B. Isolated Hip Musculature Strengthening**

All fourteen studies demonstrated that isolated strengthening exercises of hip abductors & lateral rotators for two to four times per week up to three to eight weeks duration is effective in relieving pain and improving knee function compared to quadriceps strengthening and non-exercise interventions. Kooiker et al. reported variations in quadriceps, hip and hip-quadriceps strengthening protocols in selected studies, and opined for the unavailability of standardized protocols for PFP [36]. The common hip exercise protocol included hip abduction against an elastic band while standing, and with weights in a side-lying position coupled with hip lateral rotation against an elastic band while seated and hip extension (3 sets of 10 repetitions). Conversely, quadriceps strengthening in all studies generally involved weight-bearing and non-weight-bearing exercises such as closed kinetic chain exercises, seated knee extension, leg press, squatting and stretching of hamstrings and quadriceps (3 sets of 10 repetitions).

The hip protocol generally resulted in improved pain and knee function after three to eight weeks of training, with long-term effects observed as late as twelve months post-intervention [24]. Four studies evaluated comparative therapeutic value of quadriceps versus hip muscles strengthening in treating PFP [6,37,38,40]. One study by Khayambashi et al. reported superiority of hip muscles strengthening strategy over the quadriceps strengthening for both pain and functional improvement in PFP [40]. The remaining three studies opined that isolated hip and quadriceps strengthening strategy have comparable therapeutic value for the PFP [6,37,38]. However, a meta-analysis of the effect measures (pain and function) as measured on VAS and LEFS or WOMAC revealed that hip strengthening significantly favours over the standard quadriceps strengthening (p<0.001) in PFP treatment [6,38,40].

**C. Surplus Therapeutic Effect of Hip Muscles Strengthening**

Though the proximal strengthening exercises involving quadriceps and hip muscles are commonly effective in treating PFP, Kooiker et al., Peters &Tyson opined that a combination of hip-quadriceps strategy could add the therapeutic outcome for the patients with PFP [6,14,36–38]. The present systematic review included five RCTs to examine the surplus therapeutic outcome of hip-quadriceps strengthening exercises over the standard quadriceps [4,24,39,41,42]. All studies except one supported that hip-quadriceps strategy was superior to the standard quadriceps [42].

The findings of these five RCTs have both internal and external validity and are, therefore, acceptable. Furthermore, meta-analysed data of these five studies strongly indicated that quadriceps coupled with hip muscles strengthening has significant surplus therapeutic benefits over the
conventional quadriceps or the hip exercises in the treatment of PFP (p<0.001). Therefore, a hip-quadriceps strategy should be adopted in clinical practices for pain relief and optimal functional improvements in patients with PFP.

**Limitations**

The summarised pieces of evidence supported by meta-analyses indicate that strengthening of hip muscles is effective in treating PFP for pain and knee function of physically active male/female adolescents and adults. However, a few but important limitations must be noted;

1. This systematic review and meta-analysis initially were intended to review a minimum of 20 studies to examine the therapeutic outcome of hip muscles strengthening versus quadriceps alone on pain and knee functions for patients with PFP. The expanded literature search yielded only 14 studies that are adequate for systematic review limits the strength and generalisability of the summarised findings over a wider population of patients with PFP.

2. Avraham et al. study (included in this review) used a non-exercise (electrotherapy) as a co-intervention that might have uni-directionally augmented the therapeutic effects [37].

3. Though the proportion of females to males is higher in all studies (included in this review), but this may not be considered as a limitation to generalisability for a wider group of patients with PFP, because it truly reflects the characteristics of patients with PFP that would be encountered in day-to-day clinical practice.

**Implications for routine physiotherapy practice**

The evidence from the present review has important implications in routine clinical practice for the patients with PFP:

1. Strong shreds of evidence favour hip muscles strengthening exercises for two to four times a week, up to three to four weeks, to have effective therapeutic outcome compared to standard quadriceps strengthening exercises alone in patients with PFP. This implies that therapists should consider hip muscles strengthening as standard therapeutic measures while treating patients with PFP.

2. Meta-analysis of the effect measures (both pain and function) has strongly supported that hip muscles coupled with quadriceps (hip-quad) strengthening has superior therapeutic effects compared to the individual isolated hip or quadriceps strengthening exercises. This evidence strongly implies that therapists should consider a combination of hip and quadriceps strengthening exercises for the treatment of patients with PFP. However, this may imply longer therapy sessions plus more sessions per week that may influence patient's compliance to intervention, especially if prescribed as self-efficacy [51].

3. In the present review, only one study [24] out of fourteen had followed patients up to twelve months, which was a good attempt to determine the long-term therapeutic effect of hip versus quadriceps strengthening exercises on PFP and knee function. This is indicative of evidence to be generalised only for the short-term, instead of long-term pain and functional outcomes.

**Future Research**

Must consider stratification of patients/results based on the symptom duration before the intervention, to eliminate the effect of time-delay modification on pain and functional outcomes following hip muscles strengthening in patients with PFP.

**Conclusion**

The results of this systematic review and meta-analysis indicate that isolated strengthening of hip abductors and lateral rotators has therapeutic benefits compared to quadriceps strengthening alone for the treatment of PFP. It is also clear that the hip-quadriceps strategy gives a greater therapeutic outcome than isolated quadriceps or hip muscles strengthening. Therefore, we recommend developing a hip-quadriceps exercise strategy for the treatment of PFP to encourage improved compliance, even in unsupervised patients.

</table>
Mean age: 41 yrs.

**Hip adduction/leg-press Exercise (LPHA) group:** (N=29) - (8 men; 21 women); Mean ±SD age: 38.6 ±10.8 yrs. Mean ±SD duration of symptoms: 41.8 ±36.1 months.

**Leg-press Exercise only (LP) group** (N=30) - (8 men; 22 women); Mean ±SD age: 40.2 ±9.9 yrs. Mean ±SD duration of symptoms: 38.3 ±34.2 months.

**No Exercise group (N= 30)** - (4 men; 26 women); Mean ±SD age: 43.9 ±9.8 yrs. Mean ±SD duration of symptoms: 27.7 ±41.0 months.

**Follow-up:** Immediately and at 8 wks. post-intervention.

**LP group:**
Significant improvements in VAS-W ratings (p<0.005) with mean difference of 2.58 (3.56-1.61) and Leg Lysholm scale (p<0.005) with a mean score difference of 10.93 (7.27-14.59; 95% CI).

**Non-exercise group** had no significant pain improvements (p = 0.714-0.715)

Effect difference between LPHA and LP was not significant in VAS-W ratings (p=0.577) and TLKSS (p=0.776), respectively.

---

**Fukuda et al. (2010)**

**Randomised controlled clinical trial**

N=54 (females) Sedentary women with a confirmed diagnosis of PFP

Age range: 20-40 yrs.

**Knee and hip Exercise (KHE) group (N=25):**
Mean ±SD age: 22 ±3 yrs.
Mean ±SD duration of symptoms: 23.2 ±19.0 months

**KE group (N=24):**
Hamstrings/plantar flexors/quadriceps/iliotibial band stretches. Knee extension at an angle of 90° to 45°, Leg presses and squats at an angle of 0° to 45°, single-leg calf raises, and prone knee flexion

**Follow-up:** at 3, 6, and 12 months post-intervention

**Within KHE group change in mean NPRS scores:**
For ascending stairs at 3, 6 and 12 months post-treatment were –5.0 ±1.5 (95% CI: –5.6, –4.4), –4.5 ±1.4 (95% CI: –5.0, –4.0) and –3.3 ±1.1 (95% CI: –3.7, –2.9), respectively; (p<.05).

**Within KE group change in mean NPRS scores:**
For ascending stairs at 3, 6 and 12 months post-treatment were –1.3 ±1.2 (95% CI: –2.9, 0.3), –1.1 ±1.1 (95% CI: –1.6, –0.6) and –0.1 ±1.0 (95% CI: –
Knee Exercise (KE) group (N=24): Mean ±SD age: 23±3 yrs.

Mean ±SD duration of symptoms: 21.0 ±17.7 months

Dolak et al. (2011) Randomised Clinical Trial

N=33; Females with a confirmed diagnosis of PFP.

Age range: 16-35 yrs.

Hip group (N=17) Mean age: 25±5 yrs.

Mean ±SD duration of

Hip protocol involved combined hip abduction and external rotation in side-lying and standing positions coupled with seated hip external rotation. Participants supervised during 1 session and unsupervised during 2 weekly home-based sessions for 4 weeks.

Quadriceps group (n=16)

Quadriceps protocol involved quad sets, short-arc quads, straight leg raises and terminal knee extensions. This protocol performed for 4 consecutive weeks with full supervision. Setting: Rehabilitation facility and home.

Hip group exhibited significant improvements in pain: 47.9% (p<0.001) and knee function: 18.7% (p<0.001).

Quadriceps group exhibited significant improvements in knee function (9.3%; p=0.001) but not pain (p=0.89). Pain significantly reduced in the hip group.

0.7, 0.5), respectively: (p<.05).

For descending stairs at 3, 6 and 12 months post-treatment were –1.4 ±0.9 (95% CI: –1.7, –1.1), –0.8 ±0.9 (95% CI: –1.2, –0.4), and 0.0 ±0.9 (95% CI: –0.3, 0.3), respectively.

Within KHE group change in mean LEFS scores: at 3, 6 and 12 months post-treatment were 22.4 ±10.5 (95% CI: 18.4, 26.4), 20.7 ±11.0 (95% CI: 16.5, 24.9), and 17.9 ±9.7 (95% CI: 14.2, 21.6), respectively: (p<.05).

Within KE group change in mean LEFS scores: at 3, 6 and 12 months post-treatment were 0.4 ±5.2 (–1.7, 2.5) –1.3 ±5.3 (–3.4, 2.1) –2.9 ±4.9 (–4.9, –0.9), respectively: (p<.05).

For descending stairs at 3, 6 and 12 months post-treatment were –1.4 ±0.9 (95% CI: –1.7, –1.1), –0.8 ±0.9 (95% CI: –1.2, –0.4), and 0.0 ±0.9 (95% CI: –0.3, 0.3), respectively: (p<.05).

Within KHE group change in mean AKPS scores: at 3, 6 and 12 months post-treatment were 19.8 ±9.1 (95% CI: 16.2, 23.4), 15.8 ±8.1 (95% CI: 12.6, 19.0) and 13.1±8.3 (95% CI: 9.8, 16.4), respectively: (p<.05).

Within KE group change in mean AKPS scores: at 3, 6 and 12 months post-treatment were 2.8 ±8.9 (95% CI: –0.7, 6.3) 0.2 ±8.4 (95% CI: –3.2, 3.6), and –1.8 ±8.4 (95% CI: –5.1, 1.5), respectively: (p<.05).

*Overall KHE outcomes were superior over those of the KE group (p<.05).
Quadriceps group (n=16)
Mean age: 26±6 yrs.
Mean ±SD duration of symptoms: 27±34 months

Hip/quadriceps group (N=25)
Mean ±SD age: 22.0 ±3.0 yrs.
Mean ±SD duration of symptoms: 23.2 ±19.0 months

Hip exercise group (n=14)
Supervised isolated hip abductor strengthening to 30° in standing position.
Supervised isolated hip external rotator strengthening to 30° in the seated position.
Exercise protocol performed 3 times per week for 8 weeks.
Setting: Rehabilitation facility.

Hip exercise group (n=14)
Supervised isolated hip abductor strengthening to 30° in standing position.
Setting: Home

Non-exercise group (n=14)
Participants also prescribed 1000 mg of Omega-3 and 400 mg of calcium daily for 8 weeks.
Setting: Rehabilitation facility.

Non-exercise group (n=14)
Worst pain in the previous week assessed by VAS
Setting: Home

For interventional group:
Pain during upstairs gait reduced to 80.7% (p <0.05) at 3 months, 73.2% (p <0.05) at 6 months and 53.2% (p <0.05) at 12 months
Pain during downstairs gait reduced to 72.4% (p <0.05) at 3 months, 65.5 % (p <0.05) at 6 months and 56.9 % (p <0.05) at 12 months
Knee function score on AKPS improved to 30.1 % (p <0.05) at 3 months, 20.4 % (p <0.05) at 6 months and 19.9 % (p <0.05) at 12 months

For comparator group:
Pain during downstairs gait reduced to 21.9% (p <0.05) at 3 months, 12.5% (p <0.05) at 6 months.
At 6 months pain during upstairs gait reduced to 16.7% (p <0.05)
No significant change in both AKPS and LEFS scores at 3, 6 and 12 months.

For hip exercise group:
Exhibited significant improvements in VAS score (p <0.001):
Mean VAS score difference from baseline (7.9 ±1.7) to 8 wk. post-intervention (1.4 ±1.9) was −6.4 ±2.7, 95% CI: −7.9, −4.9 (p <0.001).

Mean VAS score difference from baseline (7.9±1.7) to 6 months post-intervention (1.7±2.7) was −6.2 ±1.4; 95% CI: −7.9, −4.3 (p <0.001).
Significant improvements were seen in WOMAC score (p <0.001):
Ismail et al. (2013)

Prospective randomised controlled trial

N=32; (23 females 9 males); with a confirmed diagnosis of PFP
Age range 18-30 yrs.

Closed kinetic chain (CKC) + hip exercise (CKCH) group (n=16); (11 women, 5 men)

Mean ±SD age: 20.8 ±2.7 yrs.
Mean ±SD duration of symptoms: not indicated

CKC group (n=16)

Hip abductors and lateral rotators strengthening exercise coupled with CKC exercises for hip/quadriceps strengthening
Hip abductor strengthening performed in a side-lying position on the non-affected side.
Lateral rotators strengthening performed while seated and hip flexed to 90°
Training sessions: 3 times per week for 6 weeks

Setting: Rehabilitation facility.

For CKCH group:
Significant improvements in VAS and Kujala scores (p <0.05).
Mean VAS score difference from baseline (5.3 ±1.6) to 6 wk. (2.0 ±1.1) post-intervention
3.2 ±0.9.
Mean Kujala score difference from baseline (71.5 ±7.8) to 6 wk. (85.1 ±6.2) post-intervention
13.7 ±5.5

Baldon et al. (2014)

Randomised, comparative-controlled single-blinded study

N=31 (Females); with a confirmed diagnosis of PFP
Age range: 18-30 yrs.

Hip exercise group (n=15);

Hip extension/lateral rotation in prone, side-lying, standing
Isometric hip abduction/lateral rotation in standing knee and hip flexion in side-lying
Pelvic drop in standing

Mean duration of symptoms:

For Hip exercise group:
Mean differences in VAS score at end of intervention (−5.2 ±1.6) and 3-months post-intervention (−5.7 ±2.3) were significant (p<0.05*). Pain reduced.
Mean difference in LEFS at end of intervention (18.9 ±12.5) and 3-months post-intervention −19.5 ±11.9) were significant (p<0.05).
| Khayambashi et al. (2014) | N=36 (18 men, 18 women); with clinical diagnosis of PFP | Hip exercise group (n=18) | Received supervised quadriceps strengthening exercises (3 times a week for 8wks). |
| | | Underwent supervised exercise programs targeting hip muscles strengthening. | 

Hip exercise protocol included hip abductor and external rotator strengthening exercises in side-lying and knee flexed to 90° while seated, respectively.

Quadriceps protocols include knee flexion to 30° coupled with partial squats.

3 times a week for 8 wks.

Setting: Rehabilitation facility |

| | | Quadriceps group (n=18) | Received supervised quadriceps strengthening exercises (3 times a week for 8wks). |
| | | Also underwent hip lateral rotation in closed kinetic chain |

Plus the standard knee exercise.

Sessions performed 3 times a week for 8 wks.)

Sessions lasted between 90 to 120 minutes with supervision by a physical therapist.

Setting: Laboratory of Intervention and Orthopaedics and Traumatology laboratory |

### Comparative control trial

| | N=36 (18 men, 18 women); with clinical diagnosis of PFP | Hip exercise group (n=18) | Underwent supervised exercise programs targeting hip muscles strengthening. |
| | | Hip exercise protocol included hip abductor and external rotator strengthening exercises in side-lying and knee flexed to 90° while seated, respectively. |

Quadriceps protocols include knee flexion to 30° coupled with partial squats.

3 times a week for 8 wks.

Setting: Rehabilitation facility |

| | | Quadriceps group (n=18) | Also underwent hip lateral rotation in closed kinetic chain |

Plus the standard knee exercise.

Sessions performed 3 times a week for 8 wks.)

Sessions lasted between 90 to 120 minutes with supervision by a physical therapist.

Setting: Laboratory of Intervention and Orthopaedics and Traumatology laboratory |

### For quadriceps group:

- Pain improved significantly (p <0.05), but not knee function (p >0.05).

- Mean difference in VAS at the end of intervention (−3.0 ± 2.4) and 3-months post-intervention (−3.6 ± 3.3) were significant (p <0.05).

- Mean difference in LEFS score at the end of intervention (−12.9 ± 7.5) and 3-months post-intervention (−12.7 ± 6.2) was not significant (p >0.05).

- Between-group difference in VAS scores only significant at 3-months post-intervention (p <0.05).

- Between-group differences not significant in VAS at any time-point

### For Hip exercise group:

- Significant improvements in VAS and WOMAC scores (p <0.001).

- Mean VAS score difference from baseline (7.63 ± 1.79) to 8 wk. (2.11 ± 1.6) and 6 months (2.00 ± 1.97) post-intervention was −5.53 ± 1.60; 95% CI and −5.64 ± 1.99; 95% CI, respectively (p <0.001).

- Mean WOMAC score difference from baseline (46.83 ± 21.86) to 8 wk. (6.22 ± 3.87) and 6 months (6.94 ± 5.70) post-intervention was −40.61 ± 20.68; 95% CI and −39.89 ± 21.35; 95% CI, respectively (p <0.001).

### For Quadriceps group:

- Significant improvements in VAS and WOMAC scores (p <0.001).

- Mean VAS score difference from baseline (6.91 ± 1.94) to 8 wk. (3.27 ± 2.19) and 6 months (4.00 ± 2.44) post-intervention was −3.64 ± 1.39; 95% CI and −2.92 ± 1.72; 95% CI, respectively (p <0.001).

- Mean WOMAC score difference from baseline (44.11 ± 22.05) to 8 wk. (8.50 ± 21.35) and 6 months (5.62 ± 5.70) post-intervention was −38.51 ± 26.45; 95% CI and −35.94 ± 24.72; 95% CI, respectively (p <0.001).
(21.89 ±16.55) and 6 months (23.16 ±14.15) post-intervention was –22.22 ±10.59; 95% CI and –20.94 ±14.30; 95% CI, respectively (p <0.001).

*Between-group difference was statistically significant p ≤0.05, where outcomes in the hip group were superior over the quadriceps group.

| Avraham et al., 2007  | RCT          | Level 2b          | ✓ Inadequate sample size (pilot study)  
✓ Participants were not truly randomized to the three intervention groups  
✓ Allocation concealment probably not done  
✓ The physiotherapist who assessed the patients was blinded to the study  
✓ Blinding of outcome assessment achieved by using patient-reported outcomes on VAS for patellofemoral pain  
✓ Evaluation scale PES |
| Baldon et al., 2014   | RCT          | level 1b          | ✓ Participants recruited a/c to sample power estimation  
✓ Participants were truly randomized by random sequences in a block randomization manner  
✓ Allocation concealment evident  
✓ Double blinding evident (participants and therapists)  
✓ Blinding of outcome assessment evident because the only patient-reported pain and function outcomes collected. |
| Dolak et al., 2011    | RCT          | level 2b          | ✓ Inadequate sample power  
✓ Participants truly randomized by random sequence or block randomization  
✓ Allocation concealment evident with a random number  
✓ Outcome assessors partially blinded to participants (probable detection bias)  
✓ Outcome assessment blinded (the only patient-reported pain and function outcomes recorded). |
| Fukuda et al., 2010   | RCT          | level 1b          | ✓ Participants recruited a/c to sample power calculation  
✓ Participants truly randomized  
✓ Allocation concealment not evident  
✓ Therapists not blinded  
✓ Incomplete outcome data managed by intention-to-treat analysis  
✓ Outcome assessment blinded (the only patient-reported pain and function outcomes recorded). |
| Fukuda et al., 2012   | RCT          | level 1b          | ✓ Participants recruited based on the calculated sample power  
✓ Participants were truly randomized  
✓ Allocation concealment not evident  
✓ Therapists not blinded  
✓ Incomplete outcome data managed by intention-to-treat analysis  
✓ Outcome assessment blinded (the only patient-reported pain and function outcomes recorded). |
| Ismail et al., 2013   | RCT          | Level 2b          | ✓ Inadequate sample power (Estimated sample power size not followed)  
✓ Random allocation of participants concealed  
✓ Therapists and assessors blinded to group allocation details  
✓ Outcome assessment blinded (the only patient-reported pain and functional outcomes) |
| Khayambashi et al. 2014 | CCT         | Level 2b          | ✓ Inadequate sample power  
✓ Participants not allocated to restive groups by random allocation  
✓ Participants and therapists not blinded  
✓ Outcome assessment blinded (the only patient-reported pain and functional outcomes) |

<td>Boling et al. (2006)</td>
<td>Pre-test and post-test 6-week intervention cohort study</td>
<td>N=28; Participants with and without PFP. Age range: 18-42 yrs. Experimental group (n=14) participants with a confirmed diagnosis of PFP (5 men, 9 women) Mean ±SD age: 24 ±6 yrs. Mean ±SD duration of symptoms: 22 ±25 months Control group (n=14) healthy participants (5 men and 9 women) Mean ±SD age: 23 ±2 yrs.</td>
<td>All participants received weight-bearing exercises focusing on strengthening of hip abductors, gluteus medius, and quadriceps strengthening coupled with lower-extremity neuromuscular control for 6 weeks. Setting: Musculoskeletal research laboratory</td>
<td>N/A</td>
<td>VAS and Functional Index Questionnaire (FIQ) administered at pre-test and post-test and the end of every week of the 6-wk intervention.</td>
<td>At the end of the intervention, the PFP participants exhibited significant improvements in both VAS (p =0.001) and FIQ (p =0.001) scores from the baseline. Based on Post hoc analyses, no significant changes in both VAS and FIQ scores were observed in the control group.</td>
</tr>
<tr>
<td>Ferber et al. (2011)</td>
<td>Cohort study (Pre-test and post-test)</td>
<td>N=25; Participants with and without PFP. Experimental group (n=15) participants with a confirmed diagnosis of PFP (5 men, 10 women) Mean ±SD age: 35.2±12.2 yrs Mean duration of symptoms not indicated. Control group (n=10) Healthy participants (4 men and 6 women) Mean ±SD age: 29.9 ±8.3 yrs Mean duration of symptoms not indicated.</td>
<td>Experimental group completed a 3-week exercise training targeting the strengthening of hip-abductor muscles. Setting: University-based clinical research laboratory</td>
<td>No exercises</td>
<td>Hip abductor muscle strength and pain (VAS) measured at baseline and after 3-week training.</td>
<td>3-week hip-abductor muscle-strengthening protocol administered to participants with PFP was effective in increasing isometric muscle strength, which improved by 32.69% from baseline (p = 0.04). Mean difference between pre-training and post-training VAS scores was 3.30 ± 1.90, (p =0.01) which translated into 43.10% reduction in VAS score.</td>
</tr>
<tr>
<td>Earl &amp; Hoch, (2011).</td>
<td>Case series; Level of evidence, 4</td>
<td>N=19; Women with a confirmed diagnosis of PFP. Age range 16-40 yrs.</td>
<td>Completed 8-weeks exercise program targeting hip and core muscles strengthening and improving dynamic malalignment. Exercises were administered in 3 phases: <strong>Phase I:</strong> Abdominal draw-in exercises, side-lying clamshells / straight-leg</td>
<td>N/A</td>
<td>Pain and function assessed at baseline, 8 weeks and 6 months post-training Pain assessed by VAS</td>
<td>Significant improvements in pain and functional ability (p&lt;0.0005). Effects lasted at least 6 months post-rehabilitation.</td>
</tr>
</tbody>
</table>
(with Pre-test and post-test design)

Mean ±SD age: 22.68 ± 7.19 yrs.
Mean duration of symptoms: 17 months (range, 1-60 months).

raises, supine arm/leg extensions, quadruped leg extensions, isometric single-legged stance (SLS), quadriceps/ hamstring/ calf stretches

**Phase II:** Isometric SLS with hip abduction, SLS quick kicks, prone/side planks, quadriceps/ hamstring/ calf/iliotibial band stretches.

**Phase III:** Monster walks, SLS, quadriceps/hamstring/ calf/iliotibial band stretches.

Setting: Both at research laboratory and rehabilitation facility settings.

---

**Tyler et al. (2006)**

Cohort study; Level of evidence, 2

N=35; Participants with and without PFP (6 men; 29 women)
Mean ±SD age: 33±16 yrs.
Mean duration of symptoms: not recorded

All participants underwent 6-week partially supervised exercise program targeting strengthening of hip and knee muscles.

Exercise protocol involved seated hip flexion, adduction, extension, abduction; Stretching of hip flexors, quadriceps, iliobibial band.

Setting: rehabilitation centre supplemented with a home exercise program manual

Pain and knee discomfort during normal activities of daily living and exercise were assessed by VAS

Mean VAS score during normal daily activities improved from 4.9 ± 0.3 to 2.7 ± 0.3 (p < 0.001)
Mean VAS score during exercise also improved from 5.8 ± 0.4 to 3.0 ± 0.4 (p< 0.001).
